13                  **Abstract**

14                  Accurate trajectory prediction is essential for autonomous driving safety at intersections. Existing deep  
15                  learning models often overlook turning behaviors, leading to curvature misestimation. This study proposes a  
16                  Turn-Aware LSTM network that explicitly encodes maneuver intentions—left, right, or straight—using  
17                  vehicle trajectories extracted from UAV footage via YOLOv8 and DeepSORT. To mitigate tracking noise, a  
18                  cumulative turning-angle strategy is introduced for robust maneuver classification. Experiments demonstrate  
19                  that the proposed model significantly improves prediction accuracy for turning maneuvers, reducing Final  
20                  Displacement Error (FDE) by 15–20% at a 3-second horizon compared to vanilla LSTM and physics-based  
21                  baselines. The findings validate the integration of maneuver-aware encoding for enhanced intersection-level  
22                  forecasting in real-time applications

26                  **1. Introduction**

30        The coexistence of Connected Autonomous Vehicles (CAVs) and Conventional Vehicles  
 31 (CONVs) on urban roads poses significant challenges to traffic safety and efficiency [1]. One of  
 32 the key components for addressing these challenges is trajectory forecasting, which enables  
 33 autonomous vehicles to anticipate potential conflicts and make informed decisions to enhance  
 34 traffic flow and safety [2]. However, many existing trajectory prediction approaches heavily rely  
 35 on external data sources, such as GPS signals and detailed road geometry, which inherently limits  
 36 their scalability and adaptability [3]. Given the complexity of urban traffic networks, a solution  
 37 that

38        uses only vehicle trajectory data to infer lane positions and turning behaviors is essential for  
 39 real-world deployment and effective decision-making.

40        Previous studies on Vehicle Trajectory Prediction (VTP) have explored various deep learning-  
 41 based approaches to improve accuracy. Notably, models such as STA-LSTM, which integrates  
 42 spatial-temporal attention mechanisms, have enhanced the interpretability of vehicle trajectory  
 43 predictions by incorporating historical trajectory patterns and interactions with neighboring  
 44 vehicles [4]. Another promising approach is the Graph Attention Network (GAT) combined with  
 45 LSTM encoders, which encodes motion data and inter-vehicle relationships to generate robust  
 46 trajectory forecasts [5]. These approaches have advanced the field, but their predictive accuracy  
 47 remains limited in urban intersections where vehicles frequently execute left turns, right turns, or  
 48 lane changes. Most models still rely on position-only trajectory data without explicitly encoding  
 49 lane-level context or maneuver intentions, leading to degraded performance precisely when  
 50 turning behavior drives safety-critical outcomes.

51        In mixed-traffic environments of connected/autonomous vehicles (CAVs) and conventional  
 52 vehicles (ConVs), accurate forecasting becomes even more important. Autonomous vehicles must  
 53 anticipate turning and lane-changing maneuvers at intersections and freeway exits to avoid  
 54 conflicts, yet conventional LSTM-based models—often trained on datasets such as NGSIM—are  
 55 constrained by fixed-camera viewpoints, occlusion, and limited spatial resolution. These  
 56 shortcomings reduce their ability to learn lane-specific functions and robustly recognize turning  
 57 intent, weakening their practical applicability in real-world traffic management [5].

58        To address these limitations, this study proposes a Turn-Aware LSTM that explicitly  
 59 integrates maneuver features—left turns, right turns, and straight-through movements—into an  
 60 encoder-decoder forecasting framework. By encoding turning intent alongside kinematic states,  
 61 the model reduces errors that typically occur during turning maneuvers, while maintaining  
 62 accuracy for straight trajectories. Importantly, this work leverages high-resolution UAV-captured  
 63 traffic data, which offers wide spatial coverage and minimizes occlusion compared to fixed-  
 64 camera datasets. The richer, more continuous data stream enables more reliable labeling of  
 65 turning behaviors and provides a realistic foundation for training and testing the proposed model.

66        Building on the above, we summarize our contributions as follows.

67        (i) It shows that explicit maneuver encoding—implemented via a 1-s cumulative heading  
 68 change and one-hot turn indicators—stabilizes maneuver recognition and yields targeted accuracy  
 69 gains where prediction is hardest: left and right turns. Improvements are concentrated on turning  
 70 ADE/FDE while leaving straight-through performance essentially unchanged.

71        (ii) It presents a Turn-Aware LSTM that augments a standard encoder-decoder with turn  
 72 features on the input side. The model is lightweight ( $\approx$ 2–3 ms per vehicle on an RTX 4090),  
 73 matching vanilla-LSTM latency and thus suitable for real-time use.

74       (iii) It provides maneuver-resolved evaluations across 1–3 s horizons against CV, vanilla  
 75 LSTM, and a Tiny Transformer. While the Transformer attains the lowest overall errors, the  
 76 Turn-Aware LSTM consistently outperforms the vanilla LSTM—most notably for 3-s turning  
 77 forecasts (~15–20% FDE reduction)—thereby isolating the benefit of maneuver encoding. The  
 78 dataset, preprocessing pipeline, and threshold sensitivity (5°/10°/15°) are documented for  
 79 reproducibility, and we discuss generalization beyond the study site as well as extensions to  
 80 LiDAR/V2X fusion and turn-aware Transformer/GNN variants.

81       The remainder of this paper is structured as follows: Section 2 reviews existing trajectory  
 82 prediction approaches, with particular attention to their limitations in handling turning maneuvers  
 83 and intersection scenarios, thereby motivating the need for maneuver-aware forecasting models in  
 84 this study. Section 3 details the research methodology, including UAV-based data collection at a  
 85 signalized intersection, preprocessing techniques for stabilizing trajectories and encoding turning  
 86 behaviors, and the design of the proposed Turn-Aware LSTM architecture. Section 4 reports the  
 87 experimental results and comparative analysis, highlighting how maneuver-aware encoding  
 88 improves prediction accuracy over baseline models and discussing challenges such as noise,  
 89 stationarity, and long-horizon drift. Finally, Section 5 concludes the paper by summarizing key  
 90 contributions, outlining implications for autonomous driving and traffic management, and  
 91 suggesting directions for broader validation and multimodal extensions.  
 92

## 93       **2. Literature Review**

94       Vehicle behaviour detection is essential for traffic monitoring research, with most existing  
 95 methods relying on vehicle trajectory analysis. Traditional machine learning techniques, such as  
 96 Fuzzy C-Means (FCM) and Support Vector Machines (SVM), have been employed to classify  
 97 vehicle trajectories. Saini et al. demonstrated the effectiveness of FCM and SVM in trajectory  
 98 classification, although these methods exhibited limitations in feature robustness[6]. Similarly,  
 99 Yao et al. [7] proposed a trajectory clustering framework that encodes trajectory depth as a fixed-  
 100 length feature sequence, while Choong et al. [8] utilized the Longest Common Subsequence  
 101 (LCSS) algorithm to measure trajectory similarity before clustering. Despite their contributions,  
 102 these traditional methods struggle to scale effectively for large datasets and dynamic traffic  
 103 conditions, limiting their applicability in real-world traffic analysis.

104       Deep learning models, particularly Long Short-Term Memory (LSTM) networks, have gained  
 105 significant traction in vehicle behaviour detection due to their capability to handle sequential data  
 106 and address vanishing gradient issues [9]. LSTMs have been successfully applied in behaviour  
 107 recognition, including robot behaviour classification and abnormal behaviour detection in video  
 108 sequences [10]. In the context of vehicle trajectory prediction, Morton et al. [11] utilized LSTMs  
 109 to predict vehicle acceleration on highways, demonstrating superiority over traditional models.  
 110 Further improvements were introduced by Ding et al. [12], who combined LSTM-based models  
 111 with Convolutional Neural Networks (CNNs) to detect unsafe driving behaviours. These studies  
 112 highlight the effectiveness of LSTM-based approaches for trajectory prediction but also expose  
 113 the limitations of current models in capturing complex spatial-temporal dependencies, particularly  
 114 in mixed-traffic environments.

115       To address the challenge of modelling interactions between multiple vehicles, researchers  
 116 have integrated attention mechanisms and graph-based models into LSTM architectures. The  
 117 Spatiotemporal Attention Long Short-Term Memory (STA-LSTM) model, introduced by Lei Lin  
 118 et al. [4], incorporates spatial-temporal attention mechanisms to enhance vehicle trajectory

120 prediction by identifying how historical trajectories and surrounding vehicles influence future  
 121 movement. Similarly, Yang and Pei [13] developed the Long-Short Term Spatio-Temporal  
 122 Aggregation (LSSTA) network, which combines transformer networks with Temporal  
 123 Convolution Networks (TCN) to improve long-term dependency modelling in vehicle behaviour  
 124 prediction. Despite these advances, many models continue to depend on external data sources,  
 125 such as GPS and road geometry, making them less adaptable to real-world scenarios.

126 Our study introduces a Turn-Aware LSTM model that exclusively relies on vehicle trajectory  
 127 data to identify lane positions and predict turning behaviours, eliminating the need for GPS or  
 128 road geometry inputs. This approach directly addresses the limitations in existing research by  
 129 emphasizing lane-specific interactions and turning behaviours to improve trajectory prediction  
 130 accuracy. The customized YOLOv8 model was trained on high-resolution drone footage collected  
 131 at intersections, allowing for enhanced vehicle detection and tracking [14]. By analysing  
 132 cumulative directional changes and displacement patterns, our model classifies turning behaviours  
 133 based on angular variations, providing a robust framework for real-time vehicle behaviour  
 134 prediction.

135 The reliance on fixed roadside cameras, such as those used in the NGSIM dataset [15], has  
 136 posed challenges for vehicle trajectory prediction due to occlusions, limited spatial resolution, and  
 137 constrained fields of view. These limitations can lead to incomplete or inaccurate vehicle  
 138 detection, particularly in high-density traffic and intersection scenarios.

139 The existing literature establishes a strong foundation for vehicle trajectory prediction using  
 140 both traditional and deep learning methods. While LSTMs and transformer-based architectures  
 141 have demonstrated promising results, most existing models continue to depend on external  
 142 infrastructure-based data, limiting their applicability in mixed-traffic environments [16][17].  
 143 More importantly, they often treat vehicle motion as a uniform process, without distinguishing  
 144 between different maneuver types. In practice, however, intersection studies consistently show  
 145 that left and right turns are far more error-prone than straight-through movements, both in terms  
 146 of prediction drift and safety risk [18][19][20]. Forecasting models that ignore these maneuver-  
 147 specific differences may achieve reasonable accuracy for straight trajectories but often show  
 148 reduced reliability during turning—arguably the very moments when accurate prediction is most  
 149 critical for avoiding conflicts.

150 In addition, many methods classify turns frame by frame, making them vulnerable to jitter,  
 151 occlusion, or noise in tracking [21][22]. This often leads to unstable maneuver recognition,  
 152 particularly during stationary periods or at the onset of a turn, thereby reducing the reliability of  
 153 downstream prediction. While prior work has laid an important foundation for vehicle trajectory  
 154 prediction, turning maneuvers remain especially challenging due to their variability and  
 155 sensitivity to noise.

156 To complement these efforts, this study introduces a Turn-Aware LSTM that incorporates  
 157 cumulative turning-angle encoding—a modest but practical refinement aimed at improving  
 158 robustness for left and right turns while preserving accuracy for straight movements.

159 By explicitly representing left, right, and straight maneuvers through one-hot vectors, the  
 160 model achieves more stable recognition and delivers improved trajectory prediction precisely  
 161 where conventional models tend to degrade: during turning maneuvers and stationary phases at  
 162 intersections.

163

### 164 **3. Methodology**

165 Traffic behavior detection plays a critical role in transportation research, particularly in the  
166 field of vehicle trajectory prediction. Traditional methods rely on trajectory analysis, using  
167 classical machine learning techniques such as Fuzzy C-Means (FCM) and Support Vector  
168 Machines (SVM) for classification. However, these methods struggle with feature robustness and  
169 scalability, particularly in dynamic traffic conditions. Recent advances in deep learning,  
170 particularly Long Short-Term Memory (LSTM) networks, have significantly improved the  
171 accuracy of trajectory prediction by modeling sequential dependencies in vehicle movement data.

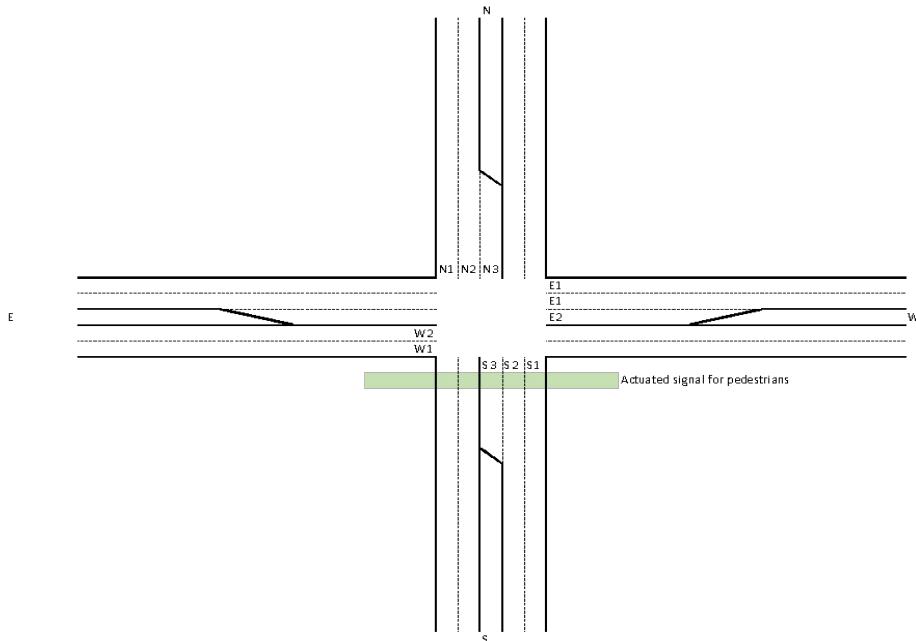

172 While existing LSTM-based models have demonstrated high accuracy in specific scenarios,  
173 they often fail to incorporate essential contextual features such as lane-specific functions and  
174 turning behaviors, which are critical for predicting vehicle movements in complex intersection  
175 environments.

176 To address these limitations, this study introduces a Turn-Aware LSTM model that explicitly  
177 encodes maneuver types (straight, left turn, right turn) alongside kinematic trajectory features.  
178 This design enables the model to learn differentiated motion dynamics across maneuvers, thereby  
179 improving prediction accuracy in exactly the situations where conventional models degrade.

180 The proposed methodology consists of five main components: data collection and  
181 preprocessing, vehicle detection and tracking, trajectory forecasting, turning behavior recognition  
182 and Turn-Aware LSTM. To ensure consistent scaling and facilitate model convergence, all  
183 numerical features were normalized before being fed into the Turn-Aware LSTM.

#### 184 *3.1 Data collection and preprocessing*

185 As shown in Fig. 1, the study site is a four-arm signalized intersection in Châteauguay,  
186 Montreal. The layout includes two westbound lanes (W1–W2), three eastbound lanes (E1–E3),  
187 three southbound lanes (S1–S3), and three northbound lanes (N1–N3). The intersection design  
188 provides dedicated turning lanes that are clearly separated from through lanes under signal  
189 control. This configuration makes the site suitable for isolating turning maneuvers in the collected  
190 vehicle trajectories. Data were recorded on December 7th and 8th, 2020, during both peak and  
191 off-peak periods to capture diverse traffic conditions. The choice of this location reflects the  
192 study's focus on turning maneuvers, as the intersection's lane geometry—with dedicated turning  
193 lanes under signal control—provides a clear setting for examining how turning behavior can be  
194 explicitly modeled in trajectory forecasting.

195

196

197

*Fig. 1 - Layout of the four-arm signalized intersection in Châteauguay, Montreal, QC*

198

199 Fig. 2 presents the temporal distribution of traffic during the data collection period, reflecting  
 200 the peak-hour congestion observed at the study site. The dataset comprises vehicles classified into  
 201 passenger vehicles, trucks, and buses, each labelled with distinct identifiers for subsequent  
 202 tracking. Video recordings were captured in 4K resolution at 30 fps, ensuring high-fidelity motion  
 203 analysis.

204

Fig. 2 - Aerial view of the study area in Châteauguay QC

208

209 Fig. 3 illustrates the UAV's position at an altitude of approximately 80 meters above the  
 210 intersection, which served as the basis for pixel-to-distance calibration. The altitude was  
 211 programmatically fixed and remained stable throughout data collection. The main source of  
 212 variability came from minor lateral drift or tilt caused by wind or GPS fluctuations. At this  
 213 elevation, each pixel corresponded to about 3.5 meters, providing a critical conversion parameter  
 214 for vehicle trajectory computation. To mitigate distortions, a Fourier–Mellin transform (FMT)  
 215 was applied for video stabilization, correcting translational, rotational, and small-scale deviations  
 216 across frames. This ensured reliable trajectory extraction, although residual perspective errors  
 217 may persist at the image periphery, a limitation acknowledged in Section 5.

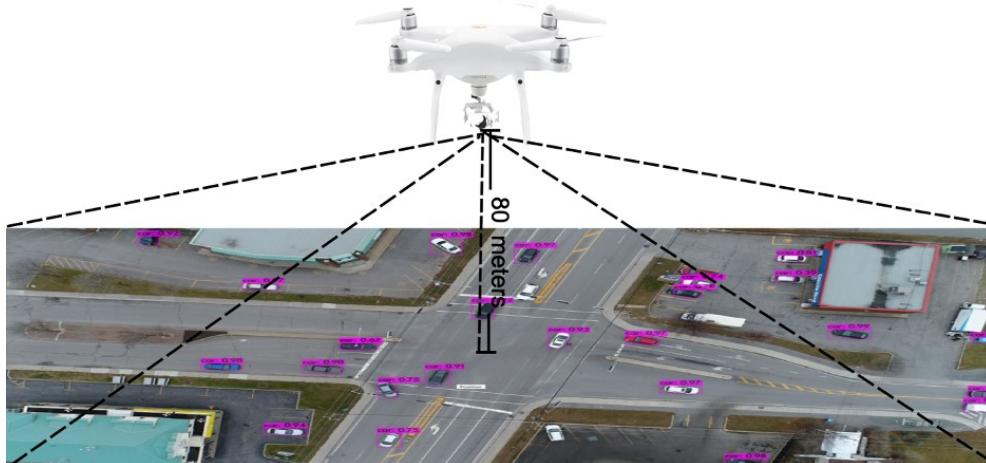

Fig. 3 - Drone positioned 80 meters above the intersection

218  
219  
220

221  
222 To improve the consistency of trajectory extraction, a Fourier-Mellin transform was applied  
223 for video stabilization, mitigating translational and rotational deviations caused by UAV  
224 movement. This method effectively corrects distortions in video frames, ensuring continuous and  
225 reliable vehicle trajectories.

226 The Fourier-Mellin transform (FMT) leverages the Fourier rotation and similarity theorems to  
227 convert rotation and scaling into translations in log-polar space. Suppose two frames are related  
228 by translation and rotation, the transformation can be expressed as Equation (1)

229

$$f_2(x, y) = f_1(x \cos \theta + y \sin \theta - t_x, -x \sin \theta + y \cos \theta - t_y) \quad (1)$$

230

where:

- $\theta$  is the rotation angle,
- $t_x$  and  $t_y$  are translations in the  $x$  and  $y$  directions, respectively.

231  
232 This transformation allows for effective compensation of rotation and scaling changes  
233 between consecutive frames, ensuring that detected vehicle trajectories remain continuous and  
234 unaffected by UAV movements.

235  
236 To formally define the Fourier-Mellin transform of a function, we use Equation (2):  
237

$$M_f(u, v) = \frac{1}{2} \int_0^{\infty} \int_0^{2\pi} f(r, \theta) r^{-ju} e^{-jv\theta} d\theta dr \quad (2)$$

238

239 where:  
240 •  $u$  and  $r$  are the Mellin transform parameters,

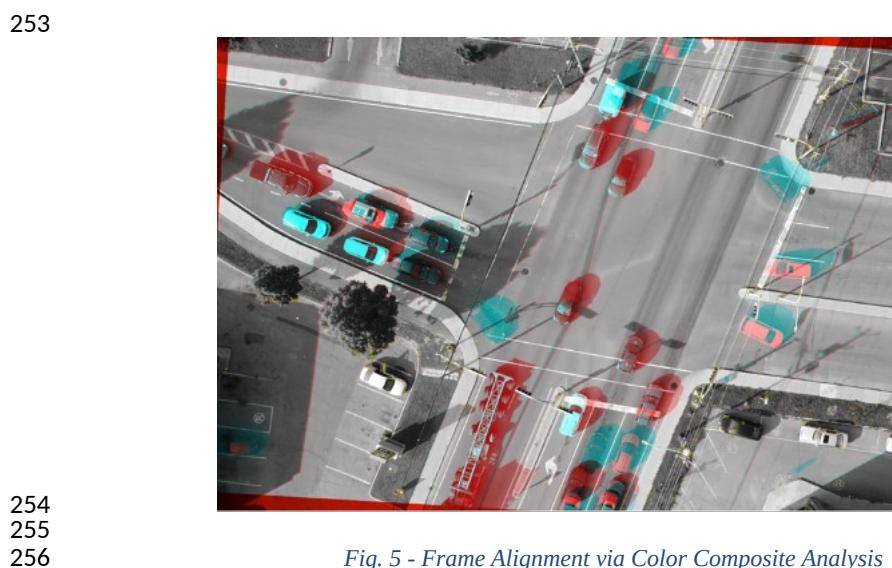

241 •  $v$  and  $\theta$  are the Fourier transform parameters.

242 This transformation remaps the Fourier-transformed frame into log-polar coordinates,  
 243 allowing rotation and scaling to be expressed as simple translations. By applying this correction,  
 244 rotational and scaling misalignments in UAV video frames are eliminated, resulting in stabilized  
 245 sequences that accurately reflect real-world vehicle movements.

246 Fig. 4 illustrates the video frames before and after the Fourier-Mellin transform, highlighting  
 247 the reduction in rotation and scaling effects. As seen in Fig. 5, color composite analysis visually  
 248 confirms the improved alignment across successive frames.  
 249

250  
 251  
 252 *Fig. 4 - Comparison of Original vs. Stabilized Frames (Fourier-Mellin Transform)*

253  
 254  
 255  
 256 *Fig. 5 - Frame Alignment via Color Composite Analysis*

257 Additionally, background subtraction techniques were employed to filter out static objects,  
 258 reducing noise and enhancing the accuracy of subsequent vehicle detection and tracking.

259  
 260 *3.2 Vehicle detection and tracking*

263 For object detection, YOLOv8 was employed due to its high precision in urban environments.  
 264 The model was retrained on a custom dataset consisting of 18,000 labeled images to adapt to site-  
 265 specific vehicle characteristics. Labeling was conducted using Open Labeling, assigning unique  
 266 class identifiers (0 to 4) to different vehicle types (passenger cars, buses, and trucks). Given the  
 267 frequent presence of stationary vehicles at intersections, dataset redundancy was minimized by  
 268 selecting frames at 150-frame intervals, ensuring a balanced dataset. To further mitigate class  
 269 imbalance, data augmentation techniques were applied, including rotation, cropping, scaling, and  
 270 flipping, thereby improving the model's robustness in detecting underrepresented turning  
 271 behaviors.

272 Vehicle trajectories were extracted using Deep SORT, which assigns unique tracking IDs  
 273 across frames based on detections from YOLOv8. Each detected vehicle was represented by its  
 274 bounding box parameters ( $x_{center}$ ,  $y_{center}$ ), width, height, confidence score, and class label. Non-  
 275 Maximum Suppression (NMS) was applied to remove redundant detections using the Intersection  
 276 over Union (IoU), as Equation (3):  
 277

$$IoU(B_i, B_j) = \frac{\text{Area}(B_i \cap B_j)}{\text{Area}(B_i \cup B_j)} \quad (3)$$

278 where overlapping bounding boxes exceeding a threshold  $\theta$  were suppressed to maintain  
 279 detection accuracy.  
 280

### 281 282 3.3 Trajectory forecasting

283 Following vehicle trajectory extraction, a data cleaning pipeline was implemented to remove  
 284 outliers and interpolate missing detections. The comprehensive end-to-end workflow, from raw  
 285 data collection to the final LSTM-based forecasting, is summarized in Figure 6.  
 286  
 287  
 288

Fig. 6 - End-to-End Vehicle Trajectory Forecasting Model

289  
290  
291292  
293  
294

After detection, vehicle velocities were computed using finite differences as Equation (4):

$$v_{x,t} = \frac{x_t - x_{t-1}}{\Delta t}, v_{y,t} = \frac{y_t - y_{t-1}}{\Delta t} \quad (4)$$

295  
296  
297

and acceleration components were estimated as Equation (5):

$$a_{x,t} = \frac{v_{x,t} - v_{x,t-1}}{\Delta t}, a_{y,t} = \frac{v_{y,t} - v_{y,t-1}}{\Delta t} \quad (5)$$

298  
299  
300

where  $\Delta t$  represents the time interval between frames. To ensure smooth and consistent velocity and acceleration estimates, a sliding window approach was applied to reduce

301 fluctuations. Additionally, forward and backward interpolation was used to handle missing  
 302 detections, ensuring seamless trajectory continuity.

303 To reduce noise, a Savitzky-Golay filter was applied separately to the x and y coordinates,  
 304 preserving motion dynamics while smoothing trajectories over a sliding window. The Savitzky-  
 305 Golay filter operates by fitting a polynomial of degree  $k$  over a window of  $2m+1$  points for each  
 306 coordinate, producing smoothed values  $x_i^{\text{smooth}}$  and  $y_i^{\text{smooth}}$ , as shown in Equation (6) and  
 307 Equation (7).

$$x_i^{\text{smooth}} = \sum_{j=-m}^m c_j x_{i+j} \quad (6)$$

$$y_i^{\text{smooth}} = \sum_{j=-m}^m c_j y_{i+j} \quad (7)$$

### 310 3.4 Turning behavior recognition

311 After trajectory preprocessing, turning behaviors were extracted and encoded to capture lane-  
 312 change and maneuvering actions, which are essential for accurate vehicle trajectory forecasting.

313 The cumulative turning angle over each 1-second window was used to classify turning  
 314 behavior as left, right, or straight.

315 To capture turning behaviors, an instantaneous direction angle was calculated using Equation  
 316 (8):

$$\phi_t = \text{atan} 2(v_{y,t}, v_{x,t}) \quad (8)$$

319 Where  $v_{x,t}$  and  $v_{y,t}$  represent the velocity components. The angular change  $\Delta\phi_t$  between  
 320 consecutive frames was then computed as Equation (9):

$$\Delta\phi_t = \phi_t - \phi_{t-1} \quad (9)$$

321 A turning threshold of  $\Theta=10^\circ$  (0.1745 rad) was adopted to classify maneuvers into left,  
 322 right, and straight categories. Heading-change thresholds are widely used in trajectory  
 323 segmentation, where turns are identified once cumulative direction changes exceed a predefined  
 324 angle [23][24][25]. Prior work shows that thresholds in the range of  $5^\circ$ – $15^\circ$  are commonly applied  
 325 to distinguish between lane-keeping and turning behavior, although the exact value depends on  
 326 data resolution and noise characteristics. To verify robustness, we conducted a sensitivity analysis  
 327 across three thresholds of  $5^\circ$ ,  $10^\circ$ , and  $15^\circ$ , and trajectory-level accuracy remained stable at  $\sim 83\%$   
 328 across all settings.

329 *Tab. 1 Sensitivity analysis results across three thresholds*

Threshold (°)	Traj Overall	Left Acc	Straight Acc	Right Acc	Curve Recall	Straight FP	Onset Delay	Label Flips	Tracks Evaluated
------------------	-----------------	-------------	-----------------	--------------	-----------------	----------------	----------------	----------------	---------------------

	<b>Acc</b>					<b>(s)</b>	<b>/100f</b>	
<b>5</b>	0.835	0.807	0.874	0.833	0.203	0.44	0.0	21.08 260
<b>10</b>	0.835	0.807	0.874	0.833	0.2	0.439	0.0	20.96 260
<b>15</b>	0.835	0.807	0.874	0.833	0.197	0.439	0.0	20.86 260

334  
335     This stability supports the adoption of  $10^\circ$  as a balanced threshold: small enough to detect true  
336 turning maneuvers, yet conservative against noise in frame-to-frame heading fluctuations. Based  
337 on this analysis, we operationalized the  $10^\circ$  rule at the frame level. At each time step  $t$ , the  
338 instantaneous direction angle  $\phi_t$  was compared against the threshold to assign a preliminary label  
339 of left, right, or straight, as shown in Equation (10):  
340  
341

$$m_t = \textcolor{red}{i} \quad (10)$$

342  
343     To mitigate noise at the frame level, the maneuver type of each trajectory was determined  
344 through aggregation rather than relying on instantaneous labels. Specifically, we applied a  
345 majority-vote strategy over the tail segment of the trajectory and required a minimum number of  
346 consecutive frames to confirm a turning event. This design ensures sensitivity to the onset of a  
347 turn while avoiding spurious fluctuations that may occur during short stops or tracking jitter.  
348

349     Because LSTM models require numerical input, maneuver categories were encoded using a  
350 one-hot representation. This choice avoids introducing artificial ordinal relationships among the  
351 three classes (left, right, straight) and ensures that each maneuver is treated as an independent  
352 behavioral mode. The encoded features were then concatenated with the kinematic states and  
353 passed into the trajectory forecasting model, providing the LSTM with both motion history and  
maneuver context.

354     The final feature vector at each time step  $t$  was structured as Equation (11):  
355

$$\mathbf{u}_t = [x_t, y_t, v_{x,t}, v_{y,t}, a_{x,t}, a_{y,t}, m_{t,1}, m_{t,2}, m_{t,3}] \quad (11)$$

356  
357     where  $m_{t,1}, m_{t,2}, \wedge m_{t,3}$  corresponded to the one-hot encoded turning classifications. The  
358 full input matrix for a vehicle's trajectory sequence was as Equation (12):  
359

$$\mathbf{U}_i = [\mathbf{u}_{t_1}, \mathbf{u}_{t_2}, \dots, \mathbf{u}_{t_n}] \quad (12)$$

360  
361     where  $n$  represents the number of time steps in the observation window.

362     Before feeding the trajectories into the prediction model, we performed consistency checks  
363 and normalization to ensure that the input data reflected physically plausible vehicle motion. This  
364 step was necessary because raw UAV-tracked trajectories can contain noise, missing detections,  
365 or unrealistic fluctuations. To address these issues, we applied the following procedures:

366     First, we identified and corrected implausible motion artifacts such as sudden position jumps,  
367 abrupt heading changes, and excessive acceleration spikes. Missing detections were handled by  
368 interpolation, either by propagating valid past or future values or by linear interpolation when  
369 both sides were available. After filling gaps, trajectories were resampled to the original frame rate  
370 of 30 fps to provide the temporal resolution required for sequential modeling.

371     Because frame-level turning cues are often noisy, turning-behavior encoding was performed  
 372     on down-sampled one-second intervals to smooth jitter, and subsequently up-sampled back to 30  
 373     fps for synchronization. Finally, all numerical features (positions, velocities, accelerations) were  
 374     normalized with respect to their maximum observed values to facilitate model convergence and  
 375     comparability across trajectories.

376     With preprocessed and normalized features in place, we proceeded to the Turn-Aware LSTM  
 377     architecture, which integrates these inputs into an encoder–decoder framework for sequence-to-  
 378     sequence trajectory forecasting.

379     3.5 *Turn-Aware LSTM*

381     The proposed predictor utilizes an encoder–decoder LSTM architecture for sequence-to-  
 382     sequence trajectory forecasting. The encoder comprises a stacked two-layer LSTM with a hidden  
 383     size of 128 units to process the observed sequence and compress temporal dependencies into final  
 384     hidden and cell states. Initialized with these states, the decoder autoregressively generates the  
 385     future trajectory for the specified prediction horizon. At each decoding step, a linear projection  
 386     maps the hidden state to 2D coordinates x and y. Training employs the Mean Squared Error loss  
 387     and the Adam optimizer with a learning rate of 0.001. To enhance generalization, an early  
 388     stopping mechanism is implemented if the validation loss remains stagnant for ten consecutive  
 389     epochs.

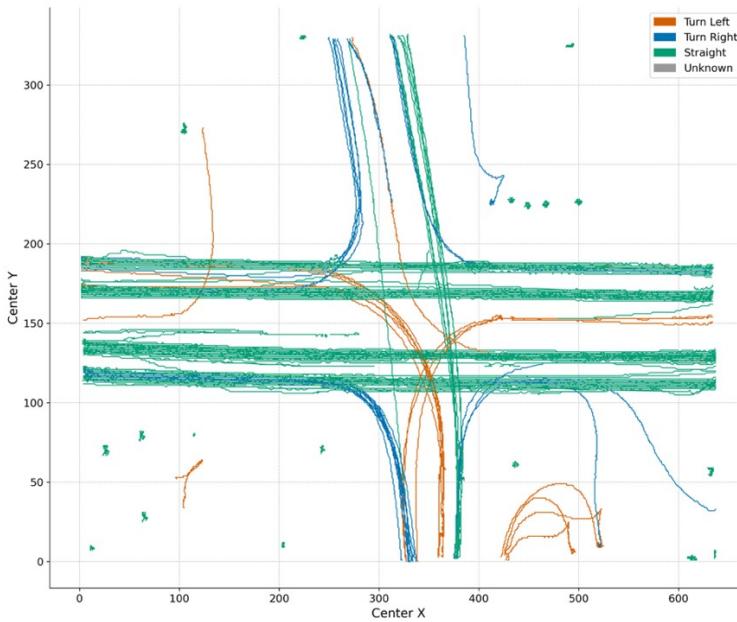

390     **4. Experiment**

392     4.1 *Experimental Setup*

393     The dataset was divided into training (70%), validation (15%), and test (15%) sets, ensuring  
 394     trajectories from the same vehicle remained within a single subset. Performance was evaluated at  
 395     horizons of 1.0 s, 2.0 s, and 3.0 s (30, 60, and 90 frames). The Turn-Aware LSTM was compared  
 396     against three baselines: (i) a physics-based Constant Velocity (CV) model; (ii) a conventional  
 397     Vanilla LSTM; and (iii) a Tiny Transformer representing the state-of-the-art. This setup isolates  
 398     the targeted accuracy gains of explicit maneuver encoding during turning maneuvers.

399     4.2 *Feature Engineering and Visualization*

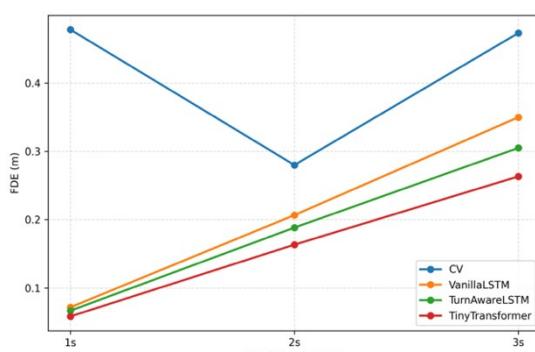

401     To illustrate the impact of maneuver encoding, Figure 7 presents vehicle trajectories  
 402     categorized into left turns, right turns, and straight movements. All trajectories were pre-  
 403     processed with y-coordinate inversion to maintain consistency with the tracking system. These  
 404     encoded behaviours serve as essential inputs, enabling the LSTM to capture complex  
 405     maneuvering patterns and improve anticipation of vehicle movements compared to raw trajectory  
 406     data.

410  
411  
412 Fig. 7 Vehicle trajectories after turning feature encoding, categorized into left turns, right turns, and straight  
413 movements.

414  
415 **4.3 Comparative Analysis across Models and Maneuvers**

416 As illustrated in Figure 8 and Figure 9 prediction errors increase with longer horizons due to  
417 accumulated uncertainty. The Tiny Transformer achieves the lowest overall Average  
418 Displacement Error (ADE) and Final Displacement Error (FDE), while the Turn-Aware LSTM  
419 consistently outperforms the Vanilla LSTM, particularly at the 3s horizon (0.30 m vs. 0.35 m  
420 FDE). The CV baseline exhibits unstable and significantly higher errors across all metrics,  
421 confirming the necessity of sequence modelling for intersection dynamics.  
422

423  
424 Fig. 8 Average FDE across all maneuvers over different prediction horizons

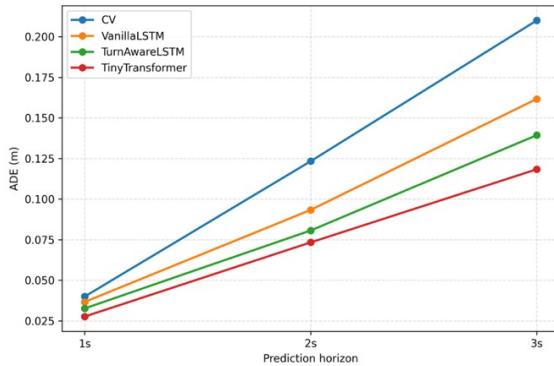

Fig. 9 Average ADE across all maneuvers over different prediction horizons

425  
426

427

The targeted benefit of turn encoding is highlighted in Figure 10 and Figure 11. For right turns, the Turn-Aware LSTM cuts the extreme drift produced by the CV model almost in half, reaching ~0.42 m at 3 s. For left turns, the model reduces error from ~0.35 m (Vanilla LSTM) to ~0.28 m at 3 s, validating the use of maneuver-aware features in curbing curvature misestimation. Performance on straight motion remains comparable across all learning-based models, confirming that turn features do not interfere with trivial forward motion. Inference times on an RTX 4090 were ~2.5 ms per trajectory, confirming the model's suitability for real-time deployment.

434

435

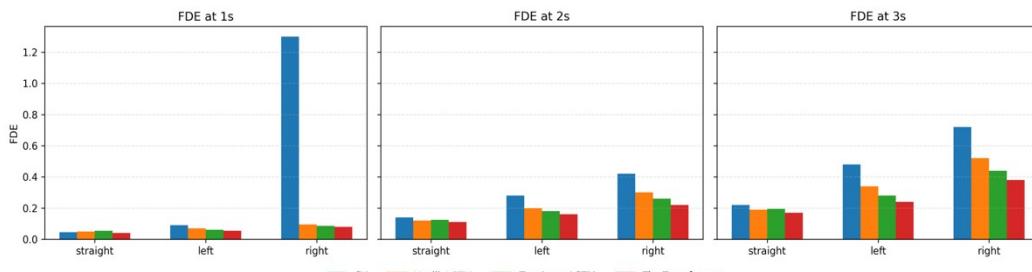

Fig. 10 FDE across all maneuvers over different prediction horizons

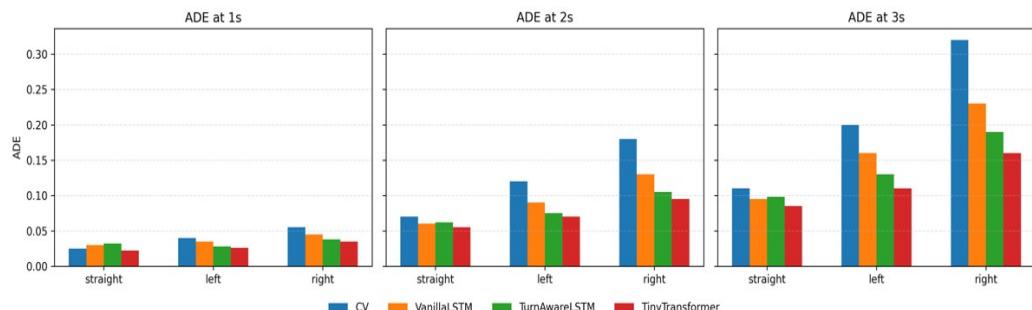

436  
437

Fig. 11 ADE across all maneuvers over different prediction horizons

438  
439

440 In addition to accuracy, we also evaluated computational efficiency. On an RTX 4090 GPU,  
 441 inference times were ~2.5 ms per trajectory for the Turn-Aware LSTM, ~2.3 ms for Vanilla  
 442 LSTM, and ~4.8 ms for Tiny Transformer, while the CV baseline was nearly instantaneous (<1  
 443 ms). This confirms that the proposed turn-aware encoding introduces only minimal overhead  
 444 compared to a standard LSTM, while remaining well within the latency requirements for real-time  
 445 deployment.

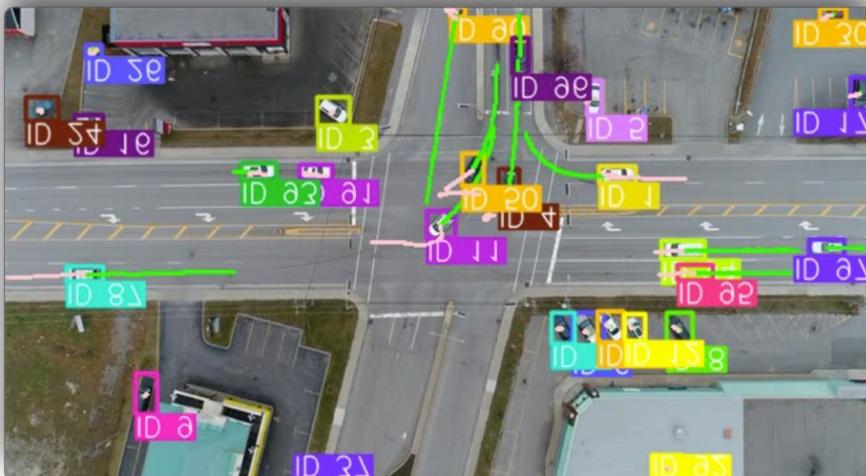

446

#### 447 4.4 Experiment Discussion

448 Turning maneuvers remain the most challenging to predict due to detection jitter, which can  
 449 cause spurious angular fluctuations during stationary periods [26]. Our experimental analysis  
 450 (formerly illustrated via frame-level labelling) revealed that vehicles waiting at red lights could be  
 451 misclassified as executing rapid turns in consecutive frames due to minor tracking noise. To  
 452 address this, we adopted a cumulative turning angle strategy that aggregates directional changes  
 453 over a 1-second window. This approach successfully smooths frame-level jitter and ensures that  
 454 the reported performance gains, such as the 20% FDE reduction for left turns, reflect genuine  
 455 improvements in trajectory prediction rather than artifacts of noisy labelling.

456 Figure 12 provides a representative snapshot of the real-time pipeline, confirming the model's  
 457 robustness. For instance, vehicles executing left and right turns (e.g., IDs 11, 50, and 1) follow the  
 458 ground truth paths closely without the curvature drift typical of vanilla LSTMs. Crucially, the  
 459 cumulative-angle method correctly identifies stationary vehicles (e.g., IDs 24 and 26) as stopped,  
 460 maintaining stable forecasts even under detection fluctuations. With a minimal computational  
 461 overhead of ~2.5 ms per trajectory, the Turn-Aware LSTM demonstrates a practical balance  
 462 between accuracy and real-time efficiency.

467

## 468 5. Conclusion

469 This study demonstrates that explicitly encoding turning behaviours via cumulative heading  
 470 changes improves vehicle trajectory forecasting, reducing FDE by 15–20% for turning maneuvers  
 471 compared to a vanilla LSTM. The model’s lightweight design (~2.5 ms inference) makes it  
 472 suitable for real-time autonomous driving and proactive traffic safety management without  
 473 reliance on GPS or detailed maps. While the Tiny Transformer achieves lower long-horizon  
 474 errors, the Turn-Aware LSTM provides targeted improvements where they matter most—at turns.  
 475 Future research will focus on integrating maneuver encoding into graph-based interaction models  
 476 and validating the framework on larger datasets like Waymo to improve robustness in high-  
 477 density, multi-agent traffic environments.

478

### 479 5.1. Data Availability Statement

480 The processed trajectory datasets, maneuver annotations, and model code are available at the  
 481 following repository: [https://github.com/Jynxzzz/Turn-Aware-LSTM\\_SUPP](https://github.com/Jynxzzz/Turn-Aware-LSTM_SUPP). Due to privacy and  
 482 data-sharing restrictions, raw video data cannot be publicly released.
